#### Abstract

The determinants of bank failure along with failure prediction have been much researched. Most of this research uses a binary approach, dividing banks into two groups—those that fail and those that do not—or predicting one of two states—failure or non-failure. However, failure is but one possible outcome. The three alternative outcomes include recovery, acquisition, or remaining a problem.

To start this paper, we study only banks that are financially distressed—those that received a poor safety and soundness rating when examined. Then we use univariate trend analysis to determine whether financial variables differ among this group of banks, depending on which future states the banks experience. This analysis suggests that meaningful relationships exist between these future states and prior period financial conditions. We then use financial ratios as explanatory variables in a unified model of bank states with the goal of improving predictions of future bank condition.

We gauge the model's effectiveness by testing the out-of-sample forecasting accuracy. Our results show that our model compares favorably with the standard bivariate failure prediction model and, yet, has the added feature of predicting recovery, merger or remaining a problem bank. Knowing these four predicted states is arguably more helpful to a deposit insurer than two-state failure forecasts: First, the FDIC's long-term strategic planning requires knowing the likely direction of all problem banks; and second, bank-regulatory policy often focuses on whether policy can affect the likelihood that troubled banks can successfully resolve their own problems.

## 1. Introduction

The determinants of bank failure along with failure prediction have been much researched. Most of this research uses a binary approach, dividing banks into two groups—those that fail and those that do not—or predicting one of two states—failure or non-failure. However, failure is but one possible outcome for financially distressed banks. We see three alternatives to bank failure: recovery, acquisition or remaining a problem.

Recognizing these three alternatives, we develop a multi-state prediction model for recovery, merger, remaining a problem, and failure. We use a sample of financially distressed commercial banks from 1990 through 2002—that received a composite CAMELS rating of either 4 or 5 when examined. Knowing the future state of banks in our sample, we construct financial profiles for each group. These profiles are then used to develop a multinomial logit estimating procedure that predicts the likelihood of a bank's future state: recovery, acquisition, remaining a problem, or failure.

Our research differs from previous research on bank failure in two ways. First, we study troubled banks only. and predict outcomes for this group. Second, we develop a multistate model that identifies financial characteristics that contribute to recovery as well as failure.

\_

<sup>&</sup>lt;sup>1</sup> CAMELS is an acronym for the five components of the regulatory rating system: Capital adequacy, Asset quality, Management, Earnings, Liquidity and market Sensitivity. Examiners have rated sensitivity only since 1998. Banks with a rating of 4 or 5 are considered problem banks. Four-rated banks generally exhibit unsafe or unsound practices or condition while 5-rated banks exhibit extremely unsafe or unsound practices of condition.

Accurate predictions of the future state of problem banks are particularly important for long-term strategic planning of the Federal Deposit Insurance Corporation—the independent deposit insurance corporation created by the Congress in 1933 to maintain stability and public confidence in the nation's banking system. When a bank goes on the problem list, a number of actions transpire (see Curry, et al., 1999, for an example of some such actions.)

Reasons that problem banks may not fail are:

## 1. Recovery because of a good economy:

A good economy allows banks with inefficiencies and problems to survive. DeYoung (1999) notes that established banks are more prone to failure during recessionary periods, and almost completely unlikely to fail during expansionary periods. He cites the large number of bank failures from the mid-1980s through the early 1990s and their causes, a series of substantial economic disruptions, including a general recession in the early 1990s and a number of regional recessions in the mid- to late 1980s. FDIC (1997) finds a strong connection between participation in regional real estate booms during the 1980s and bank failure. Total real estate loans of banks more than tripled, and commercial real estate lending quadrupled, all with much looser bank underwriting standards. When the bubble burst in the late 1980s, banks heavily exposed to real estate lending suffered a significant deterioration in loan quality that eventually caused many banks to fail.

## 2. Recovery through capital injections:

When a bank is a subsidiary of a holding company, the parent has a vested interest in keeping the subsidiary viable. French (1991) presents evidence that shows that banks with increasingly weaker CAMELS ratings have increasingly larger capital injections.<sup>2</sup> He notes that this correlation is intuitive since supervisors probably put greater pressure on undercapitalized banks to seek outside capital.

## 3. Acquisition:

Piloff and Santomero (1998) point out that one traditional view for acquisitions is that cost efficiency may be improved if the management of the acquirer is more skilled at holding down expenses for any level of activity than that of the target. However, they note that most studies fail to find a positive relationship between merger activity and gains in performance. Wheelock and Wall (2000) find that cost inefficiency reduces the probability of being acquired. Hannan and Rhoades (1987) and Hunter and Wall (1989) note that the acquirer's management may be better than the target's and could turn around the troubled bank. Ely and Song (2000) note that purchasing out-of-state banks is another common way for banking organizations to expand into new markets before the passage of the Riegle-Neal Interstate Banking and Branching Efficiency Act of 1994, which permitted banks and bank holding companies to purchase banks or establish subsidiary banks in any state.

#### 4. Remain a Problem:

-

<sup>&</sup>lt;sup>2</sup> Defined as the sum of capital stock transactions, capital contributions through mergers, and capital transactions with the parent holding company.

A bank may languish. Curry, et al (1999) note that banks are in a retrenchment mode as they approach the problem bank status; they reduce growth or shrink assets, generate new equity capital, charge-off bad loans, and increase loan-loss provisions.

The following section of this study describes previous empirical studies of bank failures, mergers and financial distress. Section three discusses our methodology; section four our data and sample; section five our results; and section six concludes.

## 2. Empirical Studies

Research on determinants of bank failures and merger activity are numerous.

Also numerous are studies on early warning systems that alert regulators of potential deterioration in banks' financial condition since the last examination.<sup>6</sup>

Previous research differs from ours in two ways. First, statistical methods used in this research include discriminant analysis, discrete-response regression techniques, or proportional hazard techniques for two-state prediction models: failure or non-failure, problem or non-problem, acquirer or target. We use multi-state logistic regression.

Second for predictions of future bank state, the sample used in previous research is failed banks versus non-failed banks or problem banks versus non-problem banks. We use only financially-distressed banks—those already a problem—as our sample.

\_

<sup>&</sup>lt;sup>6</sup> See Demirguc-Kunt, 1989, Jagtiani, et al., (2003), and King, et al., (forthcoming) for reviews of the literature.

Most previous studies use bank financial ratios that are similar to those that bank examiners review at on-site examinations: capital, asset quality, management, earnings and liquidity. Sinkey (1975) uses multiple discriminant analysis to identify financial characteristics that distinguish between problem and nonproblem banks. Stuhr and Van Wicklen (1974) also use multiple discriminant analysis to identify how financial characteristics differ between banks rated high or low (during examinations) to develop a scoring technique that provides a measure of the condition of each bank relative to other banks. Korobow, Stuhr, and Martin (1976) develop early-warning indicators from financial ratios and also a scoring technique to rank banks' resistance to adverse economic or financial developments. They use these indicators to divide banks into two groups: banks vulnerable to potential financial deterioration versus banks not vulnerable.

Research on failure prediction includes Martin (1977); Bovenzi, Marino, and McFadden (1983); Avery and Hanweck (1984); Barth, Brumbaugh, Sauerhaft (1985); Short, et al. (1985); and Thomson (1991) who use two-state prediction models, usually with a sample of failed banks and non-failed banks. Kolari, et al. (2002) develop failure prediction models using both logit and trait recognition, again a two-state model, again using failed and non-failed banks. Jagtiani, et al. (2003) also develops a two-state prediction model for bank failure, but the states predicted were capital adequacy versus capital inadequacy—where the latter state represented capital levels that fall below a

-

<sup>&</sup>lt;sup>7</sup> Sinkey defines a problem bank as one whose present or future solvency is in question, and therefore poses a risk to the FDIC insurance fund.

<sup>&</sup>lt;sup>8</sup> Barth, et al. studied failed and non-failed thrifts.

minimum threshold. In a prior study in 2000, Estrella, Park, and Peristiani use three types of capital ratios to predict bank failure. Again both studies use all banks.

Whalen (1991) adds to the binary state failure literature by using a proportional hazard model to estimate the probability that a bank with a given set of characteristics will survive longer than some specified length of time into the future. Fissel (1994) uses a similar approach to estimate actuarially-fair insurance premiums based on econometric estimates of expected time-to-failure. And DeYoung (1999) puts a twist on the approach by estimating separate hazard functions for newly-charted banks and established banks to predict time-to-failure.

Cole and Gunther (1998) use a probit model to estimate the relationship between a set of financial ratios and the likelihood of bank failure to develop an early warning system. Collier, et al. (2003) describe the FDIC's major off-site monitoring tool that supplements the current system of on-site examinations to identify institutions that have experienced noticeable financial deterioration since the last examination. This tool also uses financial ratios from previous literature on bank failures in its ordered logit prediction model of CAMELS ratings. O'Keefe, et al. (2003) add bank loan underwriting practices as an explanatory variable in predicting banks' financial deterioration since the last examination. In addition, O'Keefe, et al. use ordered logit to predict CAMELS ratings.

As with much of the literature on bank failure, the literature for acquisitions and mergers also uses binary state prediction models. Using mean difference and logit regression models, Rose (1988) identifies significant differences between acquirers and non-acquiring banks and acquired banks and non-acquired banks. O'Keefe (1996) uses logit estimations in a study for similar purposes. Wheelock and Wilson (2000) model the likelihood that a bank will fail, and then using the same variables, they model the likelihood that a bank will be acquired. Again, each of these studies uses a binary state model.

Two studies, one recent on bank failure and one less recent on mergers, deviated from the studies above by employing multinomial logit estimation procedures to predict a three-state outcome. Hannan and Rhoades (1987) predict that a bank may experience one of three outcomes: (1) Not be acquired, (2) Be acquired by a firm operating within its market, or (3) Be acquired by a firm operating outside its market. And DeYoung (2003) estimates the long-run probability of failure and acquisition in de novo banks by defining three states: (1) Failure, (2) Merger by acquisition and (3) Conversion of whole bank affiliate of a bank holding company to a branch bank of that bank holding company. Hannan and Rhoades find that adding the third state (distinguishing between merger types) yielded a number of firm and market characteristics which significantly influenced the likelihood of acquisitions that earlier studies did not. And DeYoung expects that including the other two exit states (merger by acquisition and conversion) would improve the accuracy of the failure estimates.

## 3. Methodology

Referencing previous studies, we select certain financial variables proven to be useful in determining future bank states. We use univariate trend analysis to determine whether banks that recover have different prior-period financial characteristics from banks in one of three alternative states: mergers, remaining a problem, and failure.

Prior literature on bank performance suggests a number of reasons for failure: low earnings, low liquidity, risky asset portfolios, and poor management, to name a few. Thus, we select financial variables from the same broad categories used to explain or predict binary bank states—capital adequacy, asset quality, management, earnings, and liquidity. In addition, we run a one-way analysis of variance to examine the financial characteristics of recovered banks versus banks in the remaining three states.

We use a multinomial logistic estimating procedure to model future bank state. As Long (1997) points out, a multinomial logit model is the most frequently used model for nominal outcomes. This model simultaneously estimates binary logits for pairwise comparisons among the outcome categories to a specified reference outcome. These binary logits are recover relative to failure, merge relative to failure and still a problem relative to failure.

-

<sup>&</sup>lt;sup>9</sup> Dependent variable may take multiple outcomes that cannot be ordered. In our case: Recovery, Merge, Still a problem, or Failure.

A general form of the model tested is shown in equation 1, where *Probability of*State  $(k)_{i,t}$  is the probability that bank i will be in state k at time t.

# (1) Probability of State $(k)_{i,t} = F(Financial\ condition_{i,t,t-1})$

We also estimate the model annually using a multinomial ordered logit approach. Clearly, a future state of failure is inferior to recovery, merger and remaining still a problem. Additionally, a future state of recovery is superior to any other alternative. Whether merger is superior to remaining a problem or vice versa is not, however, clear. We assume that merger would be superior to remaining a problem simply because once executed, a bank would no longer be financially distressed. Taking into account the rankings of recovery and failure provides additional information that should improve the estimation.

We gauge each model's effectiveness by testing their out-of-sample forecasting accuracy. Further, we also use bivariate bank failure models as a comparison to our multinomial models. These additional comparisons allow us to test whether including additional alternative states improves the accuracy of failure estimates over the binary model.

Two versions of the bivariate failure model are tested, one using the same explanatory variables as are used in Jarrow, et al. (2002), and a second that uses the same variables as are used in our multistate model.

Two final tests are run. The first tests whether the banks with the highest predicted probability of failure are the ones that actually fail. The second tests the economic significance of the explanatory variables.

## 4. Data

Our data consist of 3,747 occurrences of BIF-insured banks on the FDIC problem-bank list from 1990 through 2002. We divide this universe of problem banks into annual cohorts to allow us to implicitly control for the effects of economic conditions and banking legislation. Each bank has a first event and second event. The first event occurs when a bank is examined and receives a CAMELS-rating of 4 or 5. The second event occurs when the bank (1) recovers—improves to a CAMELS rating of 1, 2 or 3, (2) merges with a bank either outside of its multibank holding company or consolidates within its multi-bank holding company<sup>11</sup>, (3) remains a problem bank—continues to have a CAMELS-rating of 4 or 5 at the next examination, or (4) fails. Problem banks that have no second event are not included in the analysis. To allow for enough time to pass for changes in condition, second events are measured in the interval of 6 to 24 months after first events.

\_

10

We recognize that characteristics differ between mergers and consolidations. However, during this period, the number of consolidations is small (39). Because of the small number, we combined both events into one state.

<sup>&</sup>lt;sup>12</sup> In this paper, failure is defined as a closing resulting from an action by a regulator or an assisted merger by the FDIC.

A bank can be in several cohorts depending on when it first receives a CAMELS-rating of 4 or 5 and its outcome at the second event. If the bank still exists after the second event, its future state may be either recovered (if the CAMELS-rating improves to a 1, 2, or 3) or still a problem (if the CAMELS-rating remains a 4 or 5). When the bank goes from the problem status to the recovered status, we count it as a recovery. If it does not recover, we count it as still a problem. But the bank enters this new cohort (based on the second event) as already a problem, and we must wait until the next event to determine its future state for a second observation.

The results from the univariate trend analysis show the following characteristics of problem banks. The number of problem banks declines drastically during the 1990s as the banking crisis that began in the mid-1980s and lasted through the early 1990s subsided. As Figure 1 shows, the 1991 cohort has the highest number of problem banks, 897; the 1997 cohort has the lowest number, 62. Both the 1990 and 1998 cohorts have the highest percentage of failures, 5 percent. No problem banks fail before the second event in the 1997 or 2002 cohorts. (See Figure 2.) Most banks remain a problem at the second event, ranging from a high of 69 percent in the 1990 cohort to a low of 40 percent in the 1997 cohort, with an average of 49 percent. The proportion of banks that merge by the second event is small, ranging from 3 percent in the 1990 cohort to 20 percent in the 1998 cohort. The proportion that recovers by the second event ranges from a low of 23 percent in the 1990 cohort to a high of 53 percent in the 1997 cohort. Figure 3 shows that most problem banks that remain a problem at the second event ultimately recover. <sup>13</sup>

\_

11

<sup>&</sup>lt;sup>13</sup> The decline in the percent of still a problem banks the ultimately recover beginning in 2001 is because the second event has not yet occurred.

Jones and Critchfield (forthcoming) note three reasons that might explain the 1997 and 1998 peak years noted above for merger activity and recoveries: (1) Banks were highly profitable, liquid, and operating in favorable economic and interest-rate environments, (2) The Riegle-Neal Interstate Banking and Branching Efficiency Act of 1994 removed the remaining barriers to interstate banking and branching, and (3) A record-breaking bull market in stocks pushed market valuations of banks and thrifts to unprecedented levels, encouraging many banking firms to use their stock as currency to purchase other firms. The Nasdaq Bank Stock Index reached a high in mid-1996.

In looking at capital injections as a percentage of average assets 12-months prior to recovery, we found large increases in external injections for banks that recover peaking in 1996. Internal capital injections increased sharply from 1994 to 1995 but did not peak until 1999. (See Figure 4.)

We use data from the Consolidated Reports of Condition and Income (Call Reports) that banks file quarterly with their lead supervisory agency. We calculate beginning and ending periods of data for each bank from these Call Reports. The beginning period is calculated from the Call Report filed just before the first event and the one filed twelve months previously. Balance sheet items are averaged for the two reporting periods and taken as a ratio of average assets for the same two periods; income items are summed over the 12-month period and taken as a percent of average assets for the two periods. Similar calculations are made for the ending period of data, using the

Call Report filed immediately prior to the second event and the one filed twelve months previously.

To compare the condition and performance of banks within each state, we first group them into categories given their state at the second event. We then compare data reported at the second event to that reported for the first. Then we compute the percentage of banks with an increase between the two events for each of the measures. We expect to see that the percentages of banks with increases in performance ratios such as net income and net non-interest income that recover will be greater than the percentages in any alternative state. For expense items, we expect the opposite. In addition we expect that the percentages of banks with increases in any of the risky asset measures, high liquidity measures, and bad management that recover will be less than the percentages in any alternative state. We also expect that the percentages of banks that fail will be the greatest in these four measures. We have no expectations for the ranking of banks that merge or are still a problem except that the percentages that increase will fall between the percentages for banks that recover and those that fail.

We compare the percentages of banks in each state with increases in: Net interest income, provision for loan losses, and net non-interest income as measures of earnings; average allowance for loan and lease losses, average loans and leases past due 30-89 days, average loans and leases past due 90 days or greater, average nonaccrual loans and leases, and average other real estate owned as measures of risky asset portfolios; average risk-based capital and average tangible equity capital as measures of capital adequacy;

average volatile liabilities as a measure for liquidity; and for the management measure, we use the efficiency ratio (noninterest expense as a percent of net interest income plus noninterest income).

For the forecasts of future bank states, we select the same financial variables used in the univariate trend analysis since the univariate analysis shows a clear pattern of characteristics for each state. From the univariate trend analysis we are able to form expectations concerning the sign that coefficients on these variables will take when estimated using logit analysis. A negative coefficient implies that a marginal increase in the variable will result in the future state's becoming less likely.

Table 1 shows the expected sign of explanatory variables used in the multistate prediction model. As Table 1 shows, the "good" financial ratios (or ones associated with not failing) are: capital, capital injections, allowance for loan losses, efficiency ratio, interest income, and non-interest income. The "bad" financial ratios (those associated with failure) are those measuring poor asset quality (past due loans, non-accruing loans, real estate owned and loan charge-offs), expense items (interest expense, loss provision, salaries, expenses on premises, and other non interest expense), and volatile liquidity as measured by volatile liabilities.<sup>15</sup>

#### 5. Results

\_

<sup>&</sup>lt;sup>14</sup> For the logits we used the total income and expense items instead of netting them as we did in the univariate analysis.

<sup>&</sup>lt;sup>15</sup> Federal funds purchased and sold under agreements to repurchase, demand notes issued to the U.S. Treasury and other borrowed money, time deposits over \$100,000 held in domestic offices, foreign office deposits, trading liabilities less trading liabilities revaluation losses on interest rate, foreign exchange rate, and other commodity and equity contracts.

Our empirical results are generally in agreement with prior expectations. We find that increases in "good" or beneficial financial ratios are associated with migration to "better" bank states. Similarly, increases in "bad" or detrimental financial ratios is associated with migration to "worse bank states.

## **5.1 Univariate Trend Analysis**

The results from the univariate trend analysis are as expected. The percentages of banks with increases in "good" financial ratios are most often larger for banks in better future states and smaller for banks in worse future states. The opposite is true for banks with increases in "bad" financial ratios.

For all three earnings measures, the relative position of banks that recover is the best; the position of banks that fail is the worst for two of the three. As shown in Figure 5, 62 percent of banks that recover (825 banks) have an increase in net interest income between the first and second events, compared with 28 percent of banks that fail (33 banks). The percentages for banks that merge or are still a problem is also greater than the percentage for those that fail, but less than that for those that recover. Figures 6 and 7 show that a smaller percentage of banks that recover have an increase in expenses between the two events: Twenty-eight percent of banks that recover (372 banks) experience an increase in provision for loan losses at the second event, compared with 46 percent of banks that fail (53 banks). The percentages for banks that merge or are still a problem is less than the percentage for those that fail but greater than that for banks that recover. And, a larger percentage of banks that recover have an increase in net non-

interest income between the two events: Fifty-two percent of banks (689 banks) that recover experience an increase in net non-interest income compared with 32 percent of banks that fail (37 banks).

Our results agree with our expectations for all five assets quality measures. The relative position of banks that recover is the best; the position for those that fail is the worst. A smaller percentage of banks that recover experience increases in loan loss reserves, average loans and leases past due 30-89 days, average loans and leases past due 90 days or greater, average nonaccrual loans and leases, and average other real estate owned between the first and second events than banks that merge, remain a problem or fail. As shown in Figure 8, 50 percent of banks that recover (667 banks) experience an increase in loan loss reserves, compared with 72 percent of banks that fail (84 banks). The percentages for banks that merge or remain a problem are less than the percentage for those that fail but greater than that for banks that recover. Figure 9 shows that 36 percent of banks that recover (476 banks) experience an increase in average loans and leases past due 30-89 days, compared with 56 percent of banks that fail (65 banks). Forty-one percent of banks that recover (543 banks) experience an increase in average loans and leases past due 90 days or greater, compared with 56 percent of banks that fail (65 banks), as shown in Figure 10. Figure 11 shows that 38 percent of banks that recover (509 banks) experience an increase in nonaccrual loans and leases, compared with 61 percent of banks that fail (71 banks). Forty-four percent of banks that recover (585 banks) experience an increase in other real estate owned, compared with 76 percent of banks that fail (88 banks), as shown in Figure 12.

In line with our expectations, a larger percentage of banks that recover experience increases in average risk-based capital and average tangible equity capital between the first and second events than any alternative state. The smallest percentage of banks experiencing increases are those that fail. Figure 13 shows that 72 percent of banks that recover (952 banks) experience an increase in average risk-based capital, compared with 14 percent of banks that fail (16 banks). And Figure 14 shows that 70 percent of banks that recover (926 banks) experience an increase in average tangible equity capital, compared with 13 percent of banks that fail (15 banks).

In its 1988 study of bank failures, the Office of the Comptroller of the Currency lists over-reliance on volatile liabilities as one of the root causes of failure. Further, O'Keefe, et al. (2003) find that the percent of volatile liabilities to average assets is positively related to a CAMELS downgrade. We find, however, that banks that fail have the smallest percentage of banks with an increase in volatile liabilities between the first and second events. This result could be because management has reduced brokered deposits as required by more recent legislation. (The Federal Deposit Insurance Corporation Improvement Act of 1991 restricts activities of critically undercapitalized institutions. One such restriction is these institutions cannot pay an exceptionally large amount of interest on new or renewed liabilities.)

Twenty-six percent of banks that recover (351 banks) experience an increase in volatile liabilities compared with only 19 percent of banks that fail (22 banks), as shown in Figure 15.

A larger percentage of recovering banks experience improvements in the efficiency ratio between the first and second events than banks that merge, remain a problem or fail. Forty percent of banks that recover (832 banks) experience an increase in the efficiency ratio compared with 22 percent of banks that fail (25 banks), as shown in Figure 16.

## **5.2** Analysis of Variance

Tables 2 and 3 show results from the analysis of variance that complement the above results. Table 2 shows the mean and standard errors for each financial characteristic for each of the four states. Table 3 shows the mean differences and statistical significances for six pairings: (1) recovery versus merger, (2) recovery versus still a problem, (3) recovery versus failure, (4) still a problem versus merger, (5) still a problem versus failure, and (6) merger versus failure. The beginning period data are used in these tables.

The results reported in Table 2 show that the mean values in each of the four states for each financial variable are statistically different from zero at the first event. Further, it shows that the mean values in "good" financial ratios are most often larger for banks in better future states and smaller for banks in worse future states. The opposite is true for the mean values in "bad" financial ratios; that is, the mean values in "bad"

financial ratios are often largest for banks in worse future states than for banks in better future states.

The results reported in Table 3 show that except for two variables (capital injections from the bank holding company and capital injections from outside), the mean difference between banks that recover and those that fail are significantly different from one another, and that the position of banks that fail is usually the worst. The mean difference between banks that merge and those that fail are also significant for most variables (and the position of banks that fail is usually the worst). And, the mean difference in means between banks that are still a problem and banks that fail shows the same trends.

The results from Table 3 also indicate that there are statistically significant differences between banks that remain a problem and banks that merge and also in the pairing between recovery versus still a problem. For the pairing of still a problem versus merger, only eight variables are statistically different from one another. And for the pairing of recovery versus merger, nine variables are statistically different from one another.

Also apparent from the results reported in Table 3 is that the position for banks that remain a problem is usually in the second-worst position after those that fail. Banks that merge and those that recover are usually in the better positions.

-

<sup>&</sup>lt;sup>16</sup> The exception is that for total interest income, the position of banks that fails is the best. However, when netted against total interest expense in the univariate analysis, the position of banks that fail is the worst.

# 5.3 Logit Analysis

For our multivariate analysis, we rely on a multinomial unordered logit probability model that takes into account all four future bank states. In addition, we estimated probabilities using a multinomial ordered logit model. The univariate analysis led us to fix the ordering with recovery as the best state, followed by merger, still a problem and failure.

We did not include variables for economic condition in our model for two reasons: (1) Dividing the sample into cohorts obviates the need to include national economic variables and (2) Nuxoll, et al. (2003) did not find that state-local economic data contributed to the performance of standard offsite models.

A stepwise logit estimation procedure is used in both the ordered and unordered logits to identify those terms that have a significant relationship in predicting the likelihood that a bank will end up in one of the states: recover, merge, still a problem or failure. The stepwise estimation procedure allows us to include several measure of the same attribute in the logit model yet isolates the most important factors in terms of predicting state.

Table 4 shows summary statistics for the variables used in the logistic regressions.

The beginning period data, as explained in Section 4, are used in this table.

.

These statistics complement the results from the univariate analysis and those shown in Tables 2 and 3. The mean for banks that recover is generally higher than for banks in any of the alternative states for the "good" financial ratios; the mean for banks that fail is always the lowest, with the means for banks that merge or remaining a problem in between. (A lower efficiency ratio is associated with moving into a better state. For this ratio, the mean for banks that recover is the lowest; for banks that fail, it is the highest.) For the "bad" financial ratios, the means for banks that recover are generally the lowest.

We estimate the logits for each of our cohorts, 1990 through 2002. However, because of the small number of failures, beginning with the 1994 logit, we combine cohorts. The 1994 model is a combination of the 1993 and 1994 cohorts and the 1995 model combines 1993 through 1995. We continue combining cohorts up to 5 years (the 1993 through 1997 cohorts for the 1997 logit). For the 1998 models through 2002 we use a panel of the most recent previous 5 years.

Tables 5 through 7 show the results. The reference state is failure so the coefficients are interpreted relative to failure. Asset quality variables, loan-loss provisioning, and capital are more often statistically significant at the 1 percent, 5 percent or 10 percent level than other variables. Further they have the right signs (as expected from Table 1). Remember that a negative coefficient means that an increase in a variable will result in the future state becoming less likely. For example, in the 1990 model, loans past due 30 to 89 days is significant and has a negative sign for all three states versus

failure. An increase in this variable will result in a future state of recovery, merger or still a problem becoming less likely relative to failure.

Table 8 shows the results of the ordered logistic regression specified in equation (2) above. As noted above, the lower-ordered states are recover and merge; the higher-ordered: still a problem and fail. A positive coefficient implies the ratio enhances moving into lower-ordered (recover, merge) states and a negative one implies the opposite (moving into a higher-ordered [still a problem, fail] state). Generally speaking, all results are in agreement with our prior expectations.

Increases in tangible equity capital, capital injections, and performance ratios such as total income and total non-interest income increase the probability of moving into lower-ordered states.

Increases in risky assets such as loans past due 30 to 89 days, loans past due 90 days, non-accrual loans, and other real estate owned decrease the probability of moving into a better future state. And increases in expense items (which decrease earnings) such as total interest expense, expenses on premises, salaries, other non-interest expense, and loan-loss provision decrease the probability of moving into a better future state. The negative and significant signs associated with volatile liabilities is also in line with our expectations.

# 5.4 Prediction of State: Out-of-Sample Results

22

Whether the logit model is accurate in predicting out-of-sample forecasts is the true measure of its contribution. To test its accuracy, we forecast future bank states using prior-period estimations from our unordered logit model on the following year's cohort.

All state predictions are determined by summing predicted state probabilities for the cohort, yielding the expected number of banks in each future state.

We then compare results from the ordered logits with the results from the unordered logit regression. Figures 17 through 20 show the results. (Figure 20 also shows the results from the binary comparison discussed below.) The overall accuracy of the forecasts are excellent.

We use a standard bivariate bank failure model to compare binary forecasts against our multi-state model. The bivariate model tested uses our multistate explanatory variables. Figure 20 shows very little difference in accuracy between the binary and unordered 4-state logit.

The second comparison is shown in Figure 21. Jarrow, et al. (2003) use variables found in conventional bank failure literature to predict bank failure within the second quarter after the Call Report is filed (also known as the Loss Distribution Model—LDM). The sample includes all banks and thrifts between December 1984 and December 2002. Instead, we run this the model on all problem banks at year-end to predict the number of

failures.<sup>17</sup> We then run our unordered logit on the same set of banks to predict failures. Because a Call Report for any given cohort can extend up to 24 months beyond the year of the cohort, we use the predicted betas from one cohort to predict outcomes for troubled banks two years ahead. The Jarrow bivariate model, however only requires a one-year prediction horizon so one would expect an advantage for the bivariate model. As Figure 21 shows, the two models are comparable. The advantage to ours is that we can not only predict problem bank failure, but also recoveries, mergers and banks' remaining a problem.

# 5.5 Probabilities and economic significance

To test whether the banks with the highest probability of failure are the ones that actually fail, we rank banks that our model predicts to fail in each period by their probability of failure. We, then divide them into deciles to determine that the highest decile contains the largest number of banks that actually failed. Thirty-eight of the 65 failed banks in our cohorts from 1991 through 2002 were in the tenth decile. An additional 8 banks were in the ninth decile.

To test the economic significance of the explanatory variables, we use a fairly standard approach—evaluating in-sample predicted state probabilities based on the mean

\_

<sup>&</sup>lt;sup>17</sup> Two variables of the binary model, examination interval and CAMEL ratings, were not used since our sample was troubled banks only.

<sup>&</sup>lt;sup>18</sup> For the ordered model, 36 of the 65 failed banks were in the tenth decile, and 39 of 65 were in the tenth decile for the bivariate model. Further a Pearson test of correlation between the unordered and bivariate models ranked all banks very closely (correlation of 92 percent). However, the correlation between the ordered and bivariate models differed in ranking more so (correlation 51 percent).

values of explanatory variables and how they change with marginal changes in key explanatory variables.

Our basis for comparisons is the predicted in-sample state probabilities for 1990 based on the mean values for explanatory variables in 1990. The means for the sample of banks used in model estimation for 1990 are shown in Table 9.

The predicted state probabilities evaluated at the mean for banks in the 1990 cohort are 16.41 percent for recover, 1.82 percent for merger, 80.82 percent for still a problem, and 0.95 percent for failure. Both other real estate owned and tangible equity capital were statistically significant in 1990. Table 10 shows the effects on estimated state probabilities, ceteris paribus, should each of these ratios experience a one-percentage point increase (from 2.6808 percent to 3.6808 percent of bank assets for the former and from 5.3409 percent to 6.3409 percent of bank assets for the latter). When evaluated at the mean, we see that a one-percentage point increase in other real estate owned decreases the probability of recovery by 3 percent, from 16.41 percent to 13.45 percent. Conversely, a one-percentage point increase in tangible equity capital increases the probability of recovery by 1.67 percent, from 16.41 percent to 18.08 percent. Interestingly, estimated merger probabilities are relatively unchanged in these cases, but there are compensating changes in the remaining state probabilities (since multinomial logit ensures estimated state probabilities sum to 100 percent).

## 6. Conclusions

We offer a different approach to previous failure prediction models. First, we recognize three possible future states that could be modeled as alternatives to bank failure: recovery, merging and remaining a problem. Most previous research uses a binary approach. Second, we focus on predicting outcomes for troubled banks only; other literature focuses on the universe of banks or thrifts.

Our results show that not only does our model compare favorably with the standard bivariate failure prediction model, it also gives banks that eventually will fail, the highest probability of failure. Further, the explanatory variables are economically significant.

Knowing these four predicted states is arguably more helpful to a deposit insurer than two-state failure forecasts: First, the FDIC's long-term strategic planning requires knowing the likely direction of all problem banks; and second, bank-regulatory policy often focuses on whether policy can affect the likelihood that troubled banks can successfully resolve their own problems.

This second point leads to possible future research: Can this model be used to determine whether certain policies helped or hurt the probability of recovery?
